ABSTRACT

Measurements are presented of boundary layers with embedded vortices and with film cooling for freestream velocities of 15, and 11 m/s. Measurements of a boundary layer with embedded vortex and no film cooling, and of a boundary layer with film cooling but no vortex are presented for freestream velocity of 15 m/s. Plots of total velocity, V , streamwise velocity, V_x , secondary flow vectors, total pressure, P_0 , and streamwise vorticity are presented for many of these test conditions.

The results show that the embedded vortices completely dominate the flow field in boundary layers with film cooling. This is indicated from the plots of V , V_x , and P_0 which show the effects of film cooling to be completely decimated in the vicinity of the vortex.

In order to conduct this study, a five-hole pressure probe was calibrated for pitch and yaw. The probe was then used to measure five pressures associated with the flow. From these pressures, total velocity and the x, y, and z components of velocity were determined.

A boundary layer profile was conducted to verify the calibration of the pressure probe, measurement procedures, and velocity computations. The results show expected boundary layer behavior with a small V_y and V_z component.

ACKNOWLEDGEMENTS

This work was supported by the Wright Aeronautical Laboratories, Wright-Patterson Air Force Base, MIPR number Fy 1455-86-N0616. Dr. Charles Mac Arthur was program monitor. The Shear Layer Research Facility and other apparatus were purchased from the NPS Research Foundation. Technical contributions were made by Dr. R. V. Westphal.

I wish to thank my God for providing me with faith, persistence, and patience required to complete this thesis. I am grateful to the United States Navy for providing me with this chance of a lifetime, and to the staff and faculty of the Naval Postgraduate School for the fine education. In particular, I wish to thank Professor Phil Ligrani for his assistance, infinite patience, and for the many long hours he spent helping me. Because of his efforts, this has been a most rewarding and interesting study. Additionally, I want to acknowledge Tom McCord for his assistance and suggestions and Charles Crow for his fine workmanship. Most importantly, I am forever grateful to Sunny, Elizabeth, and Sarah for their love, and support.

I. INTRODUCTION

The increasing need for greater efficiency in gas turbine engines has resulted in higher turbine inlet temperatures. Consequently, combustor liners and turbine blading are subjected to greater amounts of thermal stress, thermal fatigue, and creep. At present, gas turbines, such as those associated with military applications, have inlet temperatures as high as 1800 - 2000 degrees C (3270 - 3632 F) with pressures of 40 atmospheres.

Turbine parts may be protected from heat loads resulting from exposure to gas at high temperatures by using a coolant within turbine passages and along turbine surfaces. Convection cooling, impingement cooling, transpiration cooling, and film cooling are used for this purpose. Although it is possible for the cooling medium to be a substance such as liquid water or Freon - 12, most gas turbine arrangements utilize engine air bled off from the compressor and rerouted to the turbine nozzles and blading. With film cooling, compressor air is ejected from surfaces of blades and vanes. The film coolant then protects metal surfaces by forming a protective insulating film between the blades and the mainstream, and by acting as a heat sink.

The flow through a turbine cascade is extremely complex. Efforts to analytically model the flow are successful only when the fluid is considered to be inviscid. When the effects of viscosity are included, the analysis is much less effective [Ref. 1]. Because of the difficulty involved in analytical representation of the viscous portions of cascade flows, much of the work in this area is experimental in nature.

Flow visualization studies by Herzig, et al., [Ref. 2] were among the first to show the complexity of flow within the cascade. Flow visualization studies by Langston, et al., [Ref. 3] and Marchal and Sieverding, [Ref. 4] also show the detailed development and complexity of the flow through the turbine cascade. More recently, Sieverding and Van Den Bosche, [Ref. 5] have used color smoke-visualization to study the evolution of flow in cascades.

Figure 1.1 from [Ref. 6] shows the various secondary flows associated with flow in turbine cascades. As the inlet boundary layer approaches the blade's leading edge, a horseshoe vortex is formed. The point at which this formation occurs is the saddle point which is clearly shown in Figure 1.2 from [Ref. 4]. One leg of the horseshoe

vortex moves initially near the side of the blade, and then through the blade passage where it is referred to as the passage vortex. In cascade flow, the passage vortex is composed of 1) fluid from the pressure side leg of the horseshoe vortex, 2) the crossflow from the endwall boundary layer, and 3) entrained fluid from the mainstream flow, [Ref. 7]. As the passage vortex continues through the cascade, it is forced by the pressure gradient to the opposite side of the passage near the suction side of the adjacent blade. This shift is clearly shown in Figure 1.3 from [Ref. 2]. The second leg of the horseshoe vortex follows the suction side of the blade and has a sense of rotation opposite to that of the pressure side vortex. This vortex moves away from the corner and is generally believed to be smaller in size than the passage vortex. As can be seen from Figure 1.4 from [Ref. 8] the passage vortex makes approximately one rotation as it passes through the cascade. In Figure 1.1 the number of revolutions has been exaggerated for clarity.

The objective of this thesis is to study the effects of embedded vortices on a film cooled turbulent boundary layer. In order to understand the effects that this complex flow field has upon heat transfer, vortex characteristics and their interaction with surrounding flow must be understood. In this study, a five-hole pressure probe is used to measure vortex characteristics.

Extensive procedures for calibration and qualification of the five-hole pressure probe, and its use in measuring three-dimensional flows are first discussed. Results of six different test are then given: 1) a baseline measurement in a developing boundary layer, 2) a boundary layer with film cooling only at a freestream velocity of 15 m/s, 3) a boundary layer with a single embedded vortex and without film cooling at a freestream velocity of 15 m/s, 4) a boundary layer with embedded vortex and film cooling at a freestream velocity of 15 m/s, 5) a boundary layer with an embedded vortex and no film cooling at a freestream velocity of 20 m/s, and 6) a boundary layer with embedded vortex and film cooling at a freestream velocity of 11 m/s. Cases 3, and 4 provide the most informative results of the study; cases 5 and 6 are incidental.

II. EXPERIMENTAL APPARATUS

A. WIND TUNNEL

The wind tunnel pictured in Figure 2.1 is now described. It is an open-circuit blower tunnel used to provide uniform flow at the nozzle exit.

1. Description

The wind tunnel is designated the NPS Shear Layer Research Facility (SLRF) and was built by Aerolab. It is designed to provide uniform flow with a minimum amount of turbulence intensity. It is designed with numerous pressure taps and four 38 x 20.3 cm (15 x 8 in.) access ports along each of the side walls. The height of the top wall is adjustable to permit changes in the pressure gradient along the length of the test section. Additionally, the top wall contains numerous instrument ports for the measurement of various flow characteristics.

The air speed through the tunnel can be adjusted from 5 m/s to 40 m/s. The blower exit slips into the inlet end of the wide-angle diffuser with 1.6 mm of clearance so that the fan is isolated from the body of the wind tunnel. The diffuser inlet contains a filter and nozzle. The test section is 3.048 m (10 ft.) long and 0.6096 m (2 ft.) wide. The top is fabricated from Lexan sheet (4.76 mm thick), continuously sealed with neoprene along the edges. The tunnel's bottom wall consists of one 1.2192 m (4 ft.) long and three 0.6096 m (2 ft.) long removable and replaceable sections. These sections are all 0.6096 m (2 ft.) wide and are sealed with "O" rings around the sides. Further discussions of the wind tunnel are contained in [Ref. 9] and [Ref. 10: p. 38].

2. Qualification and Performance

Extensive qualification test of the Shear Layer Research Facility were conducted by Ligrani, [Ref. 11]. Results show that the variation of total pressure at the exit plane of the nozzle is less than 0.4% at 26 m/s and 34 m/s. Mean velocity varies less than 0.7% for the same mean freestream speeds. From five-hole pressure probe measurements, the velocity angle deviation is nowhere greater than about 0.6 degrees at the nozzle exit plane.

Profile measurements of the mean velocity and longitudinal turbulence intensity in the turbulent boundary layer developing at 20 m/s indicate normal, spanwise uniform behavior. For this qualification test, and all results which follow, the

boundary layer was tripped near the exit of the nozzle with a 1.5 mm high strip of tape. Total pressure measurements along the test section surface at the nozzle exit were uniform within 0.5% indicating spanwise uniform skin friction.

Freestream turbulence intensity was measured to be 0.00085 (8.5 one - hundredths of one percent or .085 percent) at 20 m/s increasing to 0.00095 at 30 m/s.

B. INJECTION SYSTEM

Ordinarily, the injection system provides film coolant at temperatures above ambient. The freestream air is at ambient temperature; therefore, the heat transfer would then be in a direction opposite to that which occurs in gas turbines. The coolant is injected into the boundary layer through a single row of injection holes. The injection holes are scaled relative to boundary layer thickness to be similar to those used in current turbine blade design.

For the present tests, all injected air was at ambient temperatures.

Injection system air is provided by an 71TD Ingersoll-Rand air compressor. The air is discharged from the compressor into three large storage tanks. As the schematic, Figure 2.2, shows the air flows from the storage tank through an adjustable regulator, a cut-off valve, moisture separator, flow regulator, a Fisher and Portor rotometer (full scale 9.345E-3 m/s, 19.8 SCFM, model 10A3565A). The rotometer which controls the volumetric flow rate, discharges the film coolant through a diffuser and into the injection heat exchanger and plenum chamber.

The heat exchanger and plenum chamber shown in Figure 2.3 is 0.305 x 0.508 x 0.457 m (23 x 20 x 18 in.) and is constructed of 1.27 cm (1/2 in.) plexiglass. Injection air flows over three metal plates 0.381 x 0.508 m (15 x 20 in.). The two lower plates are covered by silicon rubber heaters, 0.381 x 0.483 m (15 x 19 in.), rated at 120 volts. The heaters are controlled through a type 136 Powerstat variable autotransformer. The top surface of the chamber contains 13 plexiglass injection tubes each being 8 cm (3.15 in.) in length and with an inner diameter of 0.95 cm (3/8 in.). This corresponds to a length to diameter ratio of 8.42. The 13 injection holes discharge the coolant into the boundary layer at a 30 degree angle. There is a three-diameter spanwise spacing between the center of each hole.

Further discussion of the qualification and performance of the injection system can be found in [Ref. 10: p.23].

C. FIVE-HOLE PRESSURE PROBE

Multi-hole pressure probes are invaluable in the investigation and measurement of complex, three-dimensional flows. In particular, the five-hole probe is well suited for measurement of three mean velocity components in low speed incompressible flows.

The five-hole pressure probe used to measure pressure in this study is manufactured by United Sensors and Control Corp. (drawing number DA-125-24-F-22-CD). The probe shown in Figure 2.4 is 0.6096 m (2 ft.) in overall length with a probe diameter of 0.318 cm (0.125 in.). It is constructed of corrosion-resistant, non-magnetic stainless steel.

The five pressure holes are arranged in two different planes which intersect at the mutual hole, P_1 . The probe tip is prismatic in geometry, as shown in Figure 2.4. The centrally located P_1 hole is normal to the freestream. The pitch plane consists of P_1 , P_4 , and P_5 pressure holes. While pressure holes P_1 , P_2 , P_3 constitute the yaw plane. The distance separating P_2 and P_3 is 0.178 cm (0.070 in.), P_4 and P_5 are 0.155 cm (0.061 in.) apart. The central hole P_1 is 0.648 cm (0.255 in.) from the bottom of the probe tip. These distances were measured using a micrometer.

For calibration, the probe was positioned in a manual traversing unit manufactured by United Sensor and Control Corp., Figure 2.5. The unit was modified by the user to include a compass rose with a radius of 15.24 cm (6 in.) and a range of yaw angles from -40 to +40 degrees (0.25 degree accuracy). Additionally, the manual traversing unit positions the probe vertically in the mainstream 0 - 30.48 cm (0 - 12 in.) range. The manual traversing unit is mounted on top of a spanwise, horizontal sled. The sled is 62.23 cm (24.5 in.) wide and is designed to set in place on top of the wind tunnel's side walls. The spanwise mounting sled is designed such that the probe can be positioned 10.16 cm (4 in.) either side of centerline in increments of 0.635 cm (0.25 in.). In addition to spanwise positioning, the spanwise sled could be rotated through a range of pitch angles from -15 to +15 degrees with an accuracy of 0.5 degrees.

After the completion of the probe calibration, an automated traversing mechanism, Figure 2.6, was used for probe positioning while measuring the pressures in the experimental test cases. The probe is fixed into the automated traversing mechanism in a position of zero yaw. The traversing mechanism has two degrees of movement which allows a thorough measurement of the flow field to be conducted. Both the spanwise and vertical traversing blocks are mounted on a 20-thread per inch drive screw and two ground steel, case-hardened steel guide support shafts. Each drive

shaft is directly coupled to a SLO-SYN type MO92-FD310 stepping motor. The motors are controlled by a MITAS Two-Axis Motion Controller, Figure 2.7 The stepping motors and the controller are manufactured by Superior Electric Company. The controller directs the movement the probe in both the spanwise and vertical directions. The MITAS controller comes equipped with 2K bytes of memory and an MC68000, 16-bit microprocessor which allows the user to program the start, stop, duration, speed, acceleration and deceleration of the stepping motors.

D. DATA ACQUISITION SYSTEM

The data acquisition system, shown in Figure 2.8 rapidly acquires the voltages associated with each pressure, converts each voltage to pressure.

1. Transducers and Demodulators

The probe is connected through reinforced plastic tubing to five Celesco model LCVR differential pressure transducers. These transducers have a designed pressure range of 0 -20 cm (0 - 7.85 in.) water and produce a 15 to 45 mV volt output signal. The transducer output signal is converted to a proportional DC signal by Celesco CD 10D carrier demodulators. Each demodulator has a maximum frequency response of -3dB at 500 Hz and a maximum output noise of 10mV, peak to peak. Each transducer/carrier demodulator combination was calibrated against a Meridian 1.27 cm (0.5 in.) horizontal manometer with an accuracy of 0.002 cm (.005 in.) of water, to give typical calibration of approximately 1.0 volt per inch of water differential pressure.

2. Computers and Hardware

A Hewlett-Packard 85 microcomputer was used to acquire and process data for the calibration of the pressure probe. Configured with 64K bytes of memory and a single magnetic tape cartridge drive, the HP-85 was used to collect, store, display, and print the majority of the data required during the course of probe calibration.

For the measurement of the flow field, a Hewlett-Packard Series 300, Model 9836S computer was dedicated to the data acquisition process. The HP 9836S is equipped with a MC68000, 8 MHz 16 32-bit processor, Dual 5-1/4 inch floppy disk drives, and 1M bytes of memory. A HP 7470 two pen plotter was used for the graphic representation of data.

Each transducer carrier demodulator combination is connected directly to a HP 3498A extender which is controlled by a HP-3497A data acquisition control unit. The HP-3497A which provides precision measurement and process monitoring, is equipped with analog multiplexing and a digital voltmeter with $1\mu V$ sensitivity.

Six software programs were developed for use during the thesis. PROCAL was developed for use with the HP-85 and was used during the probe calibration phase. PRSACQ, VEL, VELC, PLOT, VECTOR were developed for use with the HP 9836S. PRSACQ is used to measure the pressures in the various flow fields. VEL and VELC are used to compute the velocity components. PLOT and VECTOR are used for the plotting of results. A thorough discussion of the programs requires an understanding of the calibration procedures and the velocity measurement techniques as discussed in Chapter Three.

III. CALIBRATION AND MEASUREMENT PROCEDURES

Prior to using the five-hole pressure probe to measure flow velocities, it is necessary to calibrate the probe to determine the dependence of yaw, pitch, static, and total coefficients on yaw and pitch angles.

A. COORDINATE SYSTEM

A right hand coordinate system, Figure 3.1 was established for use throughout the course of study. The X-axis is parallel to the streamwise direction and is positive in the downstream direction. The Y-axis is in the vertical plane and is positive from the wind tunnel's bottom wall. The Z-axis is in the vertical plane and is positive from the wind tunnel's bottom wall. The Z-axis is in the spanwise direction. The origin of the coordinate system is located on the centerline line of the bottom wall.

Yaw, β , is defined as rotation about the Y-axis and was arbitrarily defined as positive when the direction of the flow resulted in pressure P_3 being greater than P_2 . This condition corresponds to positive component of velocity in Z direction. The pitch angle, α , is defined as rotation about the Z-axis and is defined as positive when P_4 is greater than P_5 . This condition results in a positive component of velocity in the Y direction.

B. EXPERIMENTAL PROCEDURES

The five-hole pressure probe was calibrated using the method described by Treaster and Yocum, [Ref. 12].

To perform the calibration, the probe is placed in the manual traversing unit which is mounted on top of the spanwise horizontal sled as described in Chapter Two. The probe is normal to the freestream when P_2 is equal to P_3 which gives β equal to zero.

The probe was manually fixed at a predetermined yaw angle and then rotated through the pitch plane. At each point, the data acquisition system records the five pressures. Four pressure coefficients are then calculated by the PROCAL program.

Calibration of the probe was conducted over a range of yaw angles from -20 degrees to + 20 degrees in four-degree increments. The pitch angle was varied from -15 degrees to + 15 degrees in five-degree increments. This provided a cone of angles

which was sufficient for the flows to be studied in this thesis. Calibration was performed in the NPS Shear Layer Tunnel at a freestream velocity of approximately 21 m.s (68.89 ft.sec). The probe was located 1.6 m (5.3ft) from the boundary layer trip. This equates to a Reynolds number of 1.97×10^6 based on downstream distance. Static pressure was obtained from a static pressure tap on the tunnel side wall and total pressure from a Kiel probe inserted into the flow through the top wall. Static and total pressures are measured once per set of calibration points. Atmospheric pressure is used as the reference pressure.

C. CALIBRATION COEFFICIENTS

To use the probe for measurement of complex flows, it is necessary to determine the flow angles, α and β , and the local static and total pressures. This can be done by determining four non-dimensional pressure coefficients over a range of angles in both the yaw and pitch planes. The four calibration coefficients are defined as:

$$C_{p_{yaw}} = (P_2 - P_3)(P_1 - \bar{P}) \quad (\text{eqn 3.1})$$

$$C_{p_{pitch}} = (P_4 - P_5)(P_1 - \bar{P}) \quad (\text{eqn 3.2})$$

$$C_{p_{total}} = (P_1 - P_{\text{total}})(P_1 - \bar{P}) \quad (\text{eqn 3.3})$$

$$C_{p_{static}} = (\bar{P} - P_{\text{static}})(P_1 - \bar{P}) \quad (\text{eqn 3.4})$$

where

$$\bar{P} = (P_2 + P_3 + P_4 + P_5)/4 \quad (\text{eqn 3.5})$$

To be of value in measuring a flow field, the calibration coefficients must be a function of flow angle only, independent of velocity and repeatable. Figure 3.2 shows that the calibration is both independent of velocity and repeatable in the yaw plane.

As previously stated, probe calibration was conducted by fixing the yaw angle and varying the pitch angle. Theoretically, a calibration procedure of fixing the pitch angle and rotating through the yaw angles should provide identical results. However, in this study when the fixed pitch vary yaw method was attempted, the results were not identical. The trend of C_p _{pitch} vs. pitch angle showed significant scatter, and C_p _{total} vs. pitch angle was not constant for each yaw angle.

D. RESULTS

Figure 3.3 shows the variation of C_p _{yaw} with the yaw angles for various pitch angles. The response is nearly linear for all yaw angles. The results show that values of C_p _{yaw} for various pitch angles collapse on top of each other for yaw angles of -12 degrees to +8 degrees. This means that C_p _{yaw} is independent of pitch angle in this range. From -23 degrees to -15 degrees and from +8 degrees to +15 degrees, there are slight variations in the results indicating that C_p _{yaw} has a slight dependency on the pitch angle. The fact that yaw is only slightly dependent on the pitch angle allows data to be more easily processed in determination of flow velocity.

The variation of C_p _{pitch} vs. pitch angle, Figures 3.4 and 3.5, show that this coefficient is dependent on both yaw and pitch angles. The trend of C_p _{pitch} vs. pitch angle is generally linear but there are variations from that linearity for each yaw angle, and unlike the yaw plane, these variations are not restricted to any particular region.

Figures 3.4 and 3.5 show that the range of values for C_p _{pitch} is small over the range of α shown compared to the variation of C_p _{yaw} with β . [Ref. 12: pp. 27-28] attributes this to the types of surfaces on which the holes in the pitch and yaw plane are connected. Large yaw angles result in one hole being nearly aligned with the flow. This hole senses a pressure nearly equal to the total pressure of the freestream. The other hole is then blocked from the freestream and, consequently, reads a pressure much less than the freestream static pressure. The holes in the pitch plane have a different response to variation in the pitch angle. When pitched, one hole reads a pressure which is near the total pressure of the freestream, but the second hole senses a pressure which is greater than the freestream static pressure. Thus, C_p _{yaw} is a much larger number than C_p _{pitch}. The small range of C_p _{pitch} increases the scatter and uncertainty of pitch angle measurements.

The plot of C_p _{static} vs. pitch angle, Figure 3.6, shows that C_p _{static} has weak dependency on yaw and pitch angles.

C_p _{total} vs. pitch angle, Figure 3.7, indicates that for any given yaw angle, C_p _{total} is constant throughout the range of pitch angles. Here, C_p _{total} also shows a weak dependency on yaw and pitch angles.

E. INTERPOLATION AND APPLICATION

After the probe has been calibrated and the operating characteristics of the probe are known, it is possible to determine the pitch angle, yaw angle, local static and total pressures for any flow field.

The probe is positioned normal to the freestream, and at any location in the flow field, the five pressures can be measured. These five pressures are now used to calculate the experimental or local coefficients of yaw, pitch, static pressure, and total pressure.

A fifth order polynomial was fitted to the average values of C_p _{yaw}. The resulting polynomial computed using a FORTRAN program based on the least-squares method is:

$$\beta_{app} = -.158 - 7.36(M_1) + 0.135(M_1)^2 + 0.304(M_1)^3 + 0.009(M_1)^4 - 0.031(M_1)^5 \quad (\text{eqn 3.5})$$

Here, β_{app} is the approximate yaw angle, and M_1 is the local coefficient of yaw.

Knowing the approximate yaw angle and the local C_p _{pitch}, a computerized interpolation is performed to determine the pitch angle. Since the value of the pitch angle is dependent on the local C_p _{pitch} and on the yaw angle, it is necessary to perform a double interpolation. Referring to Figure 3.8, the two yaw angles, β_1 and β_2 , which bracket the approximate yaw angle are first determined. Next, the local C_p _{pitch}, M_{2a} and M_{2b} , is located between known values of C_p _{pitch} from the calibration data for each yaw angle. In Figure 3.8, these values are designated C_{11} , C_{12} , C_{21} , and C_{22} which correspond to pitch angles from the calibration data of α_{11} , α_{12} , α_{21} , and α_{22} . The bracketing pitch angle α_{1f} is determined by the following interpolation

$$(C_{11} - M_{2a})(C_{11} - C_{12}) = (\alpha_{11} - \alpha_{1f})(\alpha_{11} - \alpha_{12}) \quad (\text{eqn 3.6})$$

which rearranged gives

$$\alpha_{1f} = \alpha_{11} - (\alpha_{11} - \alpha_{12}) \cdot (C_{11} - M_{2a}) / ((C_{11} - C_{12})) \quad (\text{eqn 3.7})$$

The other bracketing pitch angle α_{2f} is found in a similar manner which gives

$$\alpha_{2f} = \alpha_{21} - (\alpha_{21} - \alpha_{22})(C_{21} - M_{2b})(C_{21} - C_{22}) \quad (\text{eqn 3.8})$$

The pitch angle for the flow α_f is found through a second interpolation which results in the relationship

$$\alpha_f = \alpha_{1f} - (\alpha_{1f} - \alpha_{2f})(\beta_1 - \beta_{app})(\beta_1 - \beta_2) \quad (\text{eqn 3.9})$$

Because C_p_{yaw} has a slight dependency on pitch, it is necessary to refine the approximate yaw angle once the local pitch angle is known. This is done with a computerized interpolation routine which is very similar to that used for the pitch angle. As shown in Figure 3.9, the pitch angles from the calibration data, α_1 and α_2 , which bracket the local pitch angle, α_f are first determined. The local C_p_{yaw} , M_{1b} , is then located between the values of C_p_{yaw} from the calibration data for α_1 . This results in C_{31} and C_{21} which correspond to yaw angles β_{11} and β_{12} . Then, by linear interpolation β_{1f} is found

$$(C_{31} - M_{1b})(C_{31} - C_{21}) = ((\beta_{11} - \beta_{1f})(\beta_{11} - \beta_{12})) \quad (\text{eqn 3.10})$$

or

$$\beta_{1f} = \beta_{11} - (\beta_{11} - \beta_{12})(C_{31} - M_{1b})(C_{31} - C_{21}) \quad (\text{eqn 3.11})$$

The same interpolation is done for α_2 which gives

$$\beta_{2f} = \beta_{21} - (\beta_{21} - \beta_{22})(C_{32} - M_{1a})(C_{32} - C_{22}) \quad (\text{eqn 3.12})$$

β_{2f} and β_{2f} are the yaw angles which bracket the yaw angle of the flow. The flows yaw angle, β_f , can be found by a second interpolation which results in the relationship

$$\beta_f = \beta_{2f} - (\beta_{2f} - \beta_{1f})(\alpha_2 - \alpha_f)(\alpha_2 - \alpha_1) \quad (\text{eqn 3.13})$$

Since local total and static pressures are not measured at each probe location, it is necessary to perform another double interpolation to compute their values. From the calibration data, the values of $C_{p_{total}}$ for each of the bracketing yaw angles and pitch angles are known. In Figure 3.10, these points are designated C_{11} , C_{12} , C_{21} , and C_{22} . An interpolation is performed to determine the $C_{p_{total}}$ corresponding to the local pitch angle. These points are designated, C_{1f} and C_{2f} . The local $C_{p_{total}}$, M_3 , is found using the relationship

$$(C_{1f} - M_3)(C_{1f} - C_{2f}) = (\beta_1 - \beta_f)(\beta_1 - \beta_2) \quad (\text{eqn 3.14})$$

which when rearranged as shown below gives the local $C_{p_{total}}$ for the flow

$$M_3 = C_{1f} - (C_{1f} - C_{2f})(\beta_1 - \beta_f)(\beta_1 - \beta_2) \quad (\text{eqn 3.15})$$

The local $C_{p_{static}}$, M_4 is found in a similar manner. Referring to Figure 3.11, the relationship for determining the local $C_{p_{static}}$ is then given by

$$M_4 = C_{3f} - (C_{3f} - C_{4f})(\beta_1 - \beta_f)(\beta_1 - \beta_2) \quad (\text{eqn 3.16})$$

F. VELOCITY COMPONENT DETERMINATION

Once the values of the local $C_{p_{total}}$ and $C_{p_{static}}$ have been determined, the local total and static pressure can be calculated and, subsequently, the total velocity at the probe tip can be determined.

The defining relationships for $C_{p_{total}}$ and $C_{p_{static}}$ can be rearranged to determine P_{total} and P_{static} :

$$P_{total} = P_1 - (C_{p_{total}})(P_1 - \bar{P}) \quad (\text{eqn 3.17})$$

$$P_{static} = \bar{P} - (C_{p_{static}})(P_1 - \bar{P}) \quad (\text{eqn 3.18})$$

By using Bernoulli's equation, the magnitude of the local total velocity is:

$$V = \sqrt{2(P_{\text{total}} - P_{\text{static}})/\rho} \quad (\text{eqn 3.19})$$

The three components of velocity can now be determined using the total velocity vector and the local pitch and yaw angles. Referring to Figure 3.1, these velocity components are given by,

$$V_x = V \cos \alpha \cos \beta \quad (\text{eqn 3.20})$$

$$V_y = V \sin \alpha \quad (\text{eqn 3.21})$$

$$V_z = V \cos \alpha \sin \beta \quad (\text{eqn 3.22})$$

G. SPATIAL RESOLUTION CORRELATION

The calculation of V_y may be influenced by the local total velocity gradient. Corrections for this effect may be made using the following relationship

$$V_{yf} = V_{yo} + (\partial U / \partial x)(ly) \quad (\text{eqn 3.23})$$

Here V_{yo} is the uncorrected value of V_y and V_{yf} is the value of V_y corrected for spatial resolution. The value of ly used was slightly greater than the distance between P_4 and P_5 (0.155 cm): a value of 0.200 cm gave constant V_y through the two-dimensional boundary layer.

H. SOFTWARE

Six programs were developed for use during this study. They are PROCAL, PRSACQ, VEL VELC, PLOT, and VECTOR. Each program is written in BASIC. PROCAL was used with the HP-85, all others were written for the HP-9836S. All of the programs are listed in Appendix C.

PROCAL is a BASIC program used for the calibration of the pressure probe. The program begins by computing the correction factor for random noise associated

with each transducer. The user is then prompted to manually calibrate each transducer against a horizontal manometer. Static pressures are input utilizing a static pressure tap on the side wall and one of the transducers. Total pressure of the freestream is input using a Keil probe inserted into freestream and a transducer. The user is next prompted to input the ambient pressure in inches of mercury. After the user has positioned the probe at the desired angles of yaw and pitch, those angles are input into the program.

The computer then acquires the five voltages from the data acquisition system, converts each voltage to a pressure in inches of water, and then calculates the yaw, pitch, total, and static coefficients of pressure. Finally, the yaw angle, pitch angle, and the four coefficients are stored on a separate file and printed out utilizing the HP-85's internal printer.

PRSACQ was used to acquire the pressures during the experiment. PRSACQ begins by prompting the user for the number spanwise and vertical data points and the resolution. A matrix of data point location is then computed. Next, the transducers are corrected for noise and calibrated against the manometer. Freestream static and total pressures are measured and ambient conditions are input. The program enters a loop which samples each pressure ten times per probe location. The local C_p_{yaw} and C_p_{pitch} are computed. Probe position, C_p_{yaw} , and C_p_{pitch} , P_1 and P_{total} are stored in a matrix. At the end of the data collection run, these values are read into a data file on a floppy disk.

VEL is used to process the raw data acquired by PRSACQ. The data is first read into computer memory. The program computes an approximate C_p_{yaw} using a polynomial fit. Next, double interpolation subroutine is used to compute local C_p_{pitch} . A second interpolation subroutine is used to refine the value of C_p_{yaw} . The values of the C_p_{pitch} and C_p_{yaw} are used in a third interpolation subroutine to compute the local C_p_{static} and C_p_{total} . The total pressure is found from the definition of C_p_{total} . The velocity at the probe tip is computed, and the x, y, and z components of velocity are determined. Probe position (y and z coordinates), total pressure, total velocity, and V_x , V_y , and V_z are stored in a matrix and then read into a data file.

VELC corrects the V_y component for spatial resolution. PLOT is used to generate graphs of streamwise velocity, total velocity, and total pressure. VECTOR is used to plot the secondary flow vectors.

IV. EXPERIMENTAL RESULTS

The study was conducted in three parts. The first was the measurement of baseline data consisting of boundary layer profiles in a two-dimensional mean flow field. The second was the measurement of the boundary layer characteristics at a freestream velocity of 15 m/s with 1) film cooling only, 2) with embedded vortex only, and 3) with both film cooling and embedded vortex. The third part was the measurement of boundary layer with vortex at 20 m/s, and measurement of boundary layer with vortex and film cooling at a freestream velocity of 11 m/s.

A. BASELINE RESULTS

The baseline boundary layer profiles were conducted at a freestream velocity of 22 m/s. For these tests, the top wall of the wind tunnel was adjusted at 20 m/s freestream velocity so that a zero pressure gradient existed within 0.15 mm water along the length of the test section. Profiles were taken at three spanwise locations $z = +2.54$ cm, $z = 0$ cm, and $z = -2.54$ cm. Figure 4.1 shows measurements of the streamwise velocity, V_x . Figure 4.2 shows measurements of V_z . Figures 4.3 and 4.4 show measurements of the normal velocity, V_y . The results of the baseline measurements indicate behavior expected of a 2-D turbulent boundary layer, since the figures show mean profiles to be spanwise uniform for all three velocity components. Figures 4.2 and 4.3 show that the V_z and the corrected V_y components are small and nearly zero as would be expected. Figure 4.4 is the plot of V_y uncorrected for spatial resolution.

B. 15M/S FREESTREAM VELOCITY RESULTS

The investigation of the flow field was conducted by using the five-hole pressure probe to measure pressures at 800 points in a spanwise plane. Data was taken at 20 different vertical locations, each having 40 spanwise locations. All 15 m/s measurements were taken at a location of 1.49 meters from the boundary layer trip or 0.39 meters from the heat transfer plate leading edge. The film cooling cases were conducted with injection air at 75% of full scale on the rotometer which corresponds to a blowing ratio (ratio of coolant to mass fluxes) of 0.50.

1. Boundary layer with film cooling

The results of boundary layer with film cooling only and no vortex are shown in Figures 4.5 to 4.8. Figure 4.5 shows contours of the streamwise velocity, Figure 4.6 shows total velocity contours, Figure 4.7 is the plot for total pressure, and Figure 4.8 shows the secondary flow vectors. Away from the wall, outside the boundary layer, the first three figures show spatially uniform behavior for V_x , V , and P_o . Secondary flow vectors are very small everywhere in Figure 4.8. Near the wall deficits of V_x , V , and P_o correspond to locations of the film cooling jets which are located about every 3.0 cm from tunnel centerline.

2. Boundary layer with vortex

The vortex is generated by using a half-delta wing which is 3.0 cm high with 7.5 cm chord and an angle of 18°. It is identical to vortex generator # 2 described by Joseph, [Ref. 10: p.76]. The vortex generator was located at a spanwise location of $z=4.79$ cm (note that the direction of $+z$ in [Ref. 10: p.75] is reversed). Figure 4.9 shows the streamwise velocity results, Figure 4.10 is a plot of the total velocity contours, Figure 4.11 is a contour plot of total pressure, and Figure 4.12 shows the secondary flow vectors. The contour plots for V_x , V , and P_o show significant deficits caused by the generator wake which is rolled up with the vortex. The center of the wake is located at $y=3.3$ cm and $z=-3.05$ cm. Figure 4.12 shows that the vortex center is located near the same location, with overall characteristics similar to a Rankine vortex. Figure 4.13 shows the streamwise vorticity contours, where the vorticity is calculated using

$$\omega_f = (\partial V_z / \partial y) - (\partial V_y / \partial z) \quad (\text{eqn 4.1})$$

The vorticity is largest near the vortex center as expected. The circulation of the vortex is estimated to be $0.2708 \text{ m}^2/\text{s}$ using the equation

$$\Gamma = \int \omega_x dA. \quad (\text{eqn 4.2})$$

3. Boundary layer with vortex and film cooling

Figure 4.14 shows the streamwise velocity contours for this case, Figure 4.15 is the total velocity contour plots, Figure 4.16 shows the results for total pressure. Figure 4.17 shows the secondary flow vectors, and Figure 4.18 is a contour plot of

vorticity. Figure 4.15, 4-16, and 4-17 show that the deficits for V_x , V , and P_0 from the film cooling are no longer present near the vortex. This result shows that the effects of film cooling are decimated by the vortex. The effect of the vortex is particularly pronounced near its downwash side. As for the previous case, Figure 4.18 shows that vorticity is again highest near the vortex center. Figure 4.19 from [Ref. 10: p.99] shows that the results of this case are consistent with previous work by Joseph which shows high heat transfer rates on the downwash side of the vortex and low heat transfer rates on the upwash side of the vortex. The circulation for this case is estimated to be $0.2708 \text{ m}^2/\text{s}$.

C. 20 M/S AND 10 M/S FREESTREAM VELOCITY RESULTS

Figure 4.20 is a plot of streamwise velocity for the case of an embedded vortex with no film cooling with a freestream velocity of 20 m/s. Figure 4.21 is a plot of the secondary flow vectors for the same case. Figure 4.22 and Figure 4.23 are for a boundary layer with embedded vortex and film cooling at 11 m/s freestream velocity. The blowing ratio for the 20 m/s case is 0.38, and the blowing ratio at 11 m/s was 0.68. The results for both cases show trends which are similar to those discussed above. The results at a freestream velocity of 11 m/s are believed to be less reliable because of disturbances at the inlet of the tunnel which propagated to the test section during the time period the data was acquired.

V. SUMMARY AND CONCLUSIONS

Measurements are presented of boundary layers with embedded vortices and with film cooling for freestream velocities of 15, and 11 m/s. Measurements of a boundary layer with embedded vortex and no film cooling, and of a boundary layer with film cooling but no vortex are presented for freestream velocity of 15 m/s. Plots of total velocity, V , streamwise velocity, V_x , secondary flow vectors, total pressure, P_0 , and streamwise vorticity are presented for many of these test conditions.

The results show that the embedded vortices completely dominate the flow field in boundary layers with film cooling. This is indicated from the plots of V , V_x , and P_0 which show the effects of film cooling to be completely decimated in the vicinity of the vortex. This result is consistent with the heat transfer results of Joseph, [Ref. 10: p.54], which shows a localized hot spot at the wall near the same location. Future film cooling injection-hole arrangements in turbine blades must be designed to compensate for hot spots due to the vortices.

In order to conduct this study, a five-hole pressure probe was calibrated for pitch and yaw. The probe was then used to measure five pressures associated with the flow. From these pressures, total velocity and the x , y , and z components of velocity were determined.

A boundary layer profile was conducted to verify the calibration of the pressure probe, measurement procedures, and velocity computations. The results show expected boundary layer behavior with a small V_y and V_z component.

It is recommended that flow visualization study of the interaction between the vortex and film cooling be conducted to enhance the understanding of this complex phenomena.

APPENDIX C UNCERTAINTY ANALYSIS

Uncertainty analysis was performed using the method originally attributed to Kline and McCormick, [Ref. 13]. Let δ_r be the uncertainty in the result and $\delta_1, \delta_2, \dots, \delta_n$ be the uncertainties associated with each independent variable. The uncertainty in the result can be expressed as

$$\delta_r = [\sum((\partial R/\partial x_i) \times (\delta_i))]^{1/2} \quad (\text{eqn C.1})$$

To determine the uncertainty of the pitch angle, α , a straight line approximation was made for α

$$\alpha = m + b(C_{p_{\text{pitch}}}) \quad (\text{eqn C.2})$$

The following independent variables were determined: $\delta_m = \pm 1.97^\circ$, $\delta_b = \pm 2.32^\circ$, and $\delta_{C_{p_{\text{pitch}}}} = \pm 0.04637$. The uncertainty of α , was determined to be $\pm 2.36^\circ$. The high uncertainty of the pitch angle is caused by the probe being highly sensitive in the pitch plane.

The uncertainty of the yaw angle, β , is determined in a similar manner. Once again, a straight line approximation is made.

$$\beta = m + b(C_{p_{\text{yaw}}}) \quad (\text{eqn C.3})$$

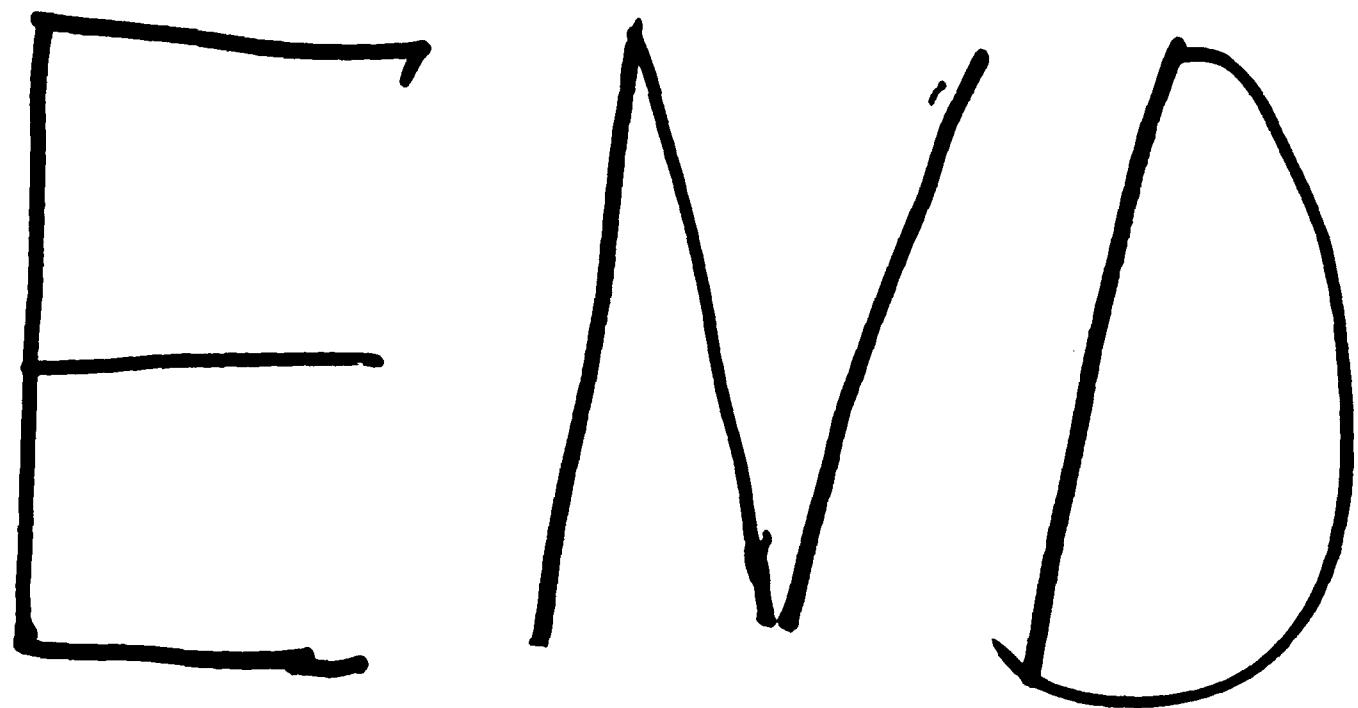

In this case, the uncertainties of the independent variables were found to be $\delta_m = \pm 0.954$, $\delta_b = 0.5924$, and $\delta_{C_{p_{\text{yaw}}}} = \pm 0.058$. From these values the uncertainty of β was calculated to be $\pm 1.29^\circ$.
